MILD METHODS FOR THE IN SITU GENERATION OF TRIMETHYLSILYL IODIDE

Michael E. Jung* and Todd A. Blumenkopf

We have shown that trimethylsilyl iodide I is a very useful reagent for a number of important organic transformations including: the dealkylative hydrolysis of ethers, esters, carbamates, and ketals; the conversion of alcohols into the corresponding iodides; the simple formation of iodomethyl methyl ether; and the formation of aldehyde iodohydrin trimethylsilyl ethers and their further reactions. Other workers have also reported its utility in dealkylations and deoxy- genations. We have described a simple two-step procedure for the preparation of trimethylsilyl iodide I from trimethylsilyl chloride, and the iodide is now commercially available from several suppliers. We now report very mild and convenient methods for the in situ generation of trimethylsilyl iodide I under completely neutral conditions.

Even though the silyl iodide is fairly easy to prepare pure, its extreme sensitivity to hydrolysis led Olah to prepare it in situ by the method of Whitmore. Namely, treatment of phenyltrimethylsilane 2 with iodine at 110°C affords an equimolar mixture of the silyl iodide I and iodobenzene 3. If one carries out this reaction in the presence of an alkyl carboxylate or alkyl phenyl ether, dealkylation is observed.

We rejected this method of in situ generation of trimethylsilyl iodide I for two primary reasons. First, one must use very high temperatures, e.g., 110°C, in order to efficiently cleave phenyltrimethylsilane with iodine. Thus all of the inherent selectivity of the dealkylation process is lost. For example, at 110°C there is little difference in the reactivity of benzyl and methyl esters or ethers, whereas the difference is very great at room temperature or below, thus
allowing the selective removal of a benzyl group in the presence of methyl. This is not possible in this in situ generation method. Secondly, iodobenzene is a necessary and unavoidable by-product in the generation of the silyl iodide from the phenylsilane. Only in the case of acids and phenols can this by-product be easily removed. Its presence becomes a serious problem in the isolation of simple alcohols formed by dealkylation of the corresponding ethers. The only general solution for its removal is the time-consuming process of column or gas chromatography. For these two major reasons, we decided to avoid this method of in situ generation and develop others.

One would expect allylic silanes to react much more rapidly with iodine than aryl silanes to generate a β-silyl iodonium iodide, which would then eliminate the silyl iodide. This is indeed the case. Treatment of allyltrimethylsilane with iodine in aprotic solvents affords trimethylsilyl iodide and allyl iodide very rapidly at room temperature or below. The reaction presumably proceeds via the iodonium iodide. If one carries out this reaction in the presence of esters, ethers, or carbamates, the corresponding trimethylsilyl esters, ethers, and carbamates are produced (Table) in high yields. The only drawback to this procedure for the in situ preparation of is the fact that allyl iodide is formed. Although it can be removed with heating on the rotary evaporator (b.p. 102°C), its high electrophilicity may make it incompatible with substrates containing nucleophilic groups, e.g. amines.

For this reason we sought a method of generation which would produce a totally unreactive and easily removable by-product. This was accomplished as follows. Treatment of benzene with lithium and trimethylsilyl chloride in tetrahydrofuran affords the 3,6-bis-trimethylsilyl-1,4-cyclohexadiene in 55% yield. When this bis-allylic silane is treated with iodine in aprotic solvents at 0°C to 25°C, there ensues a very rapid reaction which forms two equivalents of trimethylsilyl iodide and one equivalent of benzene as the only products. The intermediates in this reaction are presumably the compounds and . When this process is carried out in the presence of esters, ethers, or carbamates, clean dealkylation takes place in high yield (Table).

Therefore, compounds and are clearly superior reagents for the low-temperature in situ generation of trimethylsilyl iodide. Furthermore, one might expect from reports in the literature that these compounds would also be efficient scavengers for hydrogen iodide, producing the

a) In all cases a slight excess of the allylic silane versus iodine was used.

b) Yields were determined by integration of the pertinent peaks in the NMR spectra. Isolated yields are given in parentheses.

β-iodosilanes at low temperatures. As the times for dealkylation in the Table indicate, the bis-silyl cyclohexadiene 7 appears to scavenge hydrogen iodide very readily while the allylsilane 4 does not seem to be as effective in this regard. Thus, one can guarantee the absence of hydrogen iodide in the reaction mixture by the use of a very slight excess of the bis-silyl cyclohexadiene 7. Finally, we believe that the dealkylation observed here proceeds by the mechanism we have previously suggested and not by the trimolecular six-centered transition state proposed by Olah. Since one can observe the rapid formation of trimethylsilyl iodide in the NMR prior to dealkylation, it
is obvious that the allylic silanes 4 and 7 generate 1 without being present in the transition state for dealkylation.
